Abstract. Three edges $e_1$, $e_2$ and $e_3$ in a graph $G$ are consecutive if they form a path (in this order) or a cycle of lengths three. An injective edge coloring of a graph $G = (V,E)$ is a coloring $c$ of the edges of $G$ such that if $e_1$, $e_2$, and $e_3$ are consecutive edges in $G$, then $c(e_1) \neq c(e_2)$. The injective edge coloring number $\chi'_i(G)$ is the minimum number of colors permitted in such a coloring. In this paper, exact values of $\chi'_i(G)$ for several classes of graphs are obtained, upper and lower bounds for $\chi'_i(G)$ are introduced and it is proven that checking whether $\chi'_i(G) = k$ is NP-complete.

1. Introduction

Throughout this paper we deal with simple graphs $G$ of order $n \geq 2$ (the number of vertices) and size $m \geq 1$ (the number of edges). The vertex set and edge set will be denoted by $V(G)$ and $E(G)$, respectively. A proper vertex (edge) coloring of a graph $G$ is an assignment of colors to the vertices (edges) of $G$, that is, $c : V(G)(E(G)) \rightarrow C$, where $C$ is a set of colors, such that no two adjacent vertices (edges) have the same color, that is $c(x) \neq c(y)$ for every edge $xy$ of $G$ ($c(e) \neq c(e')$ for every pair of edges $e$, $e'$ incident on the same vertex). The (edge) chromatic number $(\chi'(G)) \chi(G)$ of $G$ is the minimum number of colors permitted in a such coloring.

Some variants of vertex and edge coloring have been considered. An injective vertex coloring of $G$ is a coloring of the vertices of $G$ so that any two vertices with a common neighbor receive distinct colors. The injective chromatic number $\chi'_i(G)$ of a graph $G$ is the smallest number of colors in an injective coloring of $G$. Injective coloring of graphs was introduced by Hahn et. al in [6] and was originated from Complexity Theory on Random Access Machines, and can be applied in the theory of error correcting codes [6]. In [6] it was proved that, for $k \geq 3$, it is NP-complete to decide whether the
injective chromatic number of a graph is at most \( k \). Note that an injective coloring is not necessarily a proper coloring, and vice versa (see [2, 6]).

The following variant of edge coloring was proposed in [3]. In a graph \( G \), three edges \( e_1, e_2 \) and \( e_3 \) (in this fixed order) are called consecutive if \( e_1 = xy, e_2 = yz \) and \( e_3 = zu \) for some vertices \( x, y, z, u \) (where \( x = u \) is allowed). In other words, three edges are consecutive if they form a path or a cycle of lengths 3. A 3-consecutive edge coloring is a coloring of the edges such that for each three consecutive edges, \( e_1, e_2 \) and \( e_3 \), the color of \( e_3 \) is one of the colors of \( e_1 \) or \( e_2 \). The 3-consecutive edge coloring number of a graph \( G, \psi_3^G(G) \), is the maximum number of colors of a 3-consecutive edge coloring of \( G \). This concept was introduced and studied in some details in [3], where it is proven that the determination of the 3-consecutive edge coloring number for arbitrary graphs is NP-hard.

An injective edge coloring (i-edge coloring for short) of a graph \( G \) is a coloring \( c : E(G) \to C \), such that if \( e_1, e_2 \) and \( e_3 \) are consecutive edges in \( G \), then \( c(e_1) \neq c(e_2) \). The injective edge coloring number or injective edge chromatic index of graph \( G, \chi'_i(G) \), is the minimum number of colors permitted in an i-edge coloring. We say that graph \( G \) is \( k \) edge i-colorable if \( \chi'_i(G) \leq k \). Note that an i-edge coloring is not necessarily a proper edge coloring, and vice versa. It is straightforward to see that for the edge chromatic number of \( G \) and the vertex chromatic number of its line graph \( L(G) \), the equality \( \chi'(G) = \chi(L(G)) \) holds. However, it is not always true that \( \chi'_i(G) = \chi_i(L(G)) \). For instance, \( \chi'_i(K_{1,n}) = 1 \) and \( \chi_i(L(K_{1,n})) = n \).

A motivation for the i-edge coloring is the following. We can model a Packet Radio Network (PRN) as an undirected graph \( G = (V, E) \), where the vertices represent the set of stations and two vertices are joined by an edge if and only if the corresponding stations can hear each other transmissions, i.e., the set of edges \( E \) represents the common channel property between the pairs of stations (see [11, 12]). Assigning channels or frequencies to the edges between stations to avoid secondary interference corresponds to the i-edge coloring of the graph (where each color is a frequency or channel).

i-edge coloring is closely related with the concept of star arboricity recently introduced by Axenovich et al. [1]. The star arboricity of a graph \( G, \text{isa}(G) \), is the smallest number of induced star-forests covering the edges of \( G \). Ferdjallah et al. [5] prove that \( \chi'_i(G) = \text{isa}(G) \).

In this paper we obtain exact values of \( \chi'_i(G) \) for several classes of graphs, give upper and lower bounds for \( \chi'_i(G) \), and we prove that checking whether \( \chi'_i(G) = k \) is NP-complete.

For basic graph terminology we refer the reader to [7].

2. Exact values of \( \chi'_i(G) \) for some classes of graphs

We start this section with a few basic results which are direct consequences of the definition of injective edge coloring number. As usually, the path, the cycle and the wheel with \( n \) vertices will be denoted by \( P_n, C_n \) and \( W_n \), respectively. (The wheel \( W_n \) with \( n \) vertices is obtained by connecting a single vertex to all vertices of \( C_{n-1} \). The wheel \( W_n \) is often a \( C_n \) with a universal vertex added.) The complete graph of order \( n \) is denoted by \( K_n \) and the complete bipartite graph with bipartite classes with \( p \) and \( q \) vertices is denoted by \( K_{p,q} \). When \( p = 1 \), the complete bipartite graph \( K_{1,n} \) is called the star of order \( q + 1 \). The star \( K_{1,n} \) is often referred to as a \( q \)-star. (In particular, \( P_2 \) is the star \( K_{1,1} \) and \( P_5 \) is the star \( K_{1,2} \)).

Considering the above notations and denoting the Petersen graph by \( P \), the following values for the injective edge coloring number can be easily derived.

Proposition 2.1.

1. \( \chi'_i(P_n) = 2 \), for \( n \geq 4 \).
2. \( \chi'_i(C_n) = \begin{cases} 2, & \text{if } n \equiv 0 \pmod{4}, \\ 3, & \text{otherwise.} \end{cases} \)
3. \( \chi'_i(K_{p,q}) = \min\{p, q\} \).
4. $\chi'_i(P) = 5$. (A feasible 5 i-edge coloring of the Petersen graph is shown in Figure 1. Note that no pair of the edges labeled 1 to 5 can receive the same color.)

Figure 1: An injective edge coloring of Petersen graph with five colors.

**Proposition 2.2.** Let $G$ be a graph. Then $\chi'_i(G) = k$ if and only if $k$ is the minimum positive integer for which the edge set of $G$, $E(G)$, can be partitioned into non-empty subsets $E_1, \ldots, E_k$, such that the end-vertices of the edges of each of these subsets $E_j$ induces a subgraph $G_j$ of $G$ where each component is a star.

Proof. Let us assume that $\chi'_i(G) = k$ and consider an injective edge coloring of the edges of $G$ using $k$ colors, $c_1, \ldots, c_k$. Then $E(G)$ can be partitioned into the subset of edges $E_1, \ldots, E_k$, where every edge in $E_j$ has the color $c_j$, for $j = 1, \ldots, k$. Then, for each $j \in [1, \ldots, k]$ the end vertices of the edges of $E_j$ must induce a graph without three consecutive edges (otherwise the color can not be the same for all the edges in $E_j$). Therefore, each component of the graph $G_j$ induced by the end vertices of the edges in $E_j$ are stars. Furthermore, the positive integer $k$ is minimum (otherwise if there exists such partition of $E(G)$ into $k' < k$ subsets of edges $E_1', \ldots, E_k'$ then $\chi'_i(G) \leq k' < k$).

Conversely, let us assume that $k$ is the minimum positive integer for which $E(G)$ can be partitioned as described. Then, taking into account the first part of this proof, it is immediate that $\chi'_i(G) = k$.  

Applying Proposition 2.2, we may conclude that the injective edge coloring number of a wheel $W_n$, with $n \geq 4$ vertices, is:

$$\chi'_i(W_n) = \begin{cases} 
6 & \text{if } n \text{ is even} \\
4 & \text{if } n \text{ is odd and } n - 1 \equiv 0 \pmod{4} \\
5 & \text{if } n \text{ is odd and } n - 1 \not\equiv 0 \pmod{4}
\end{cases}$$

From Proposition 2.2, it follows that whenever $\chi'_i(G) = k$, the adjacency matrix $A_G$ of graph $G$ can be given by

$$A_G = \sum_{j=1}^{k} A_{G_j}$$

where each $G_j$ is an induced subgraph of $G$, with at least one edge, and its components are stars or isolated vertices. Therefore, $\chi'_i(G_j) = 1$, for $j = 1, \ldots, k$, and $\chi'_i(G)$ is the minimum number of induced subgraphs $G_j$ satisfying the conditions of Proposition 2.2.

Now, let us characterize the extremal graphs with largest and smallest injective chromatic index.

**Proposition 2.3.** For any graph $G$ of order $n \geq 2$, $\chi'_i(G) = 1$ if and only if $G$ is the disjoint union of $k \geq 1$ stars, i.e., $G = \bigcup_{j=1}^{k} K_{1,l_j}$, with $\sum_{j=1}^{k} l_j = n - k$ and $V(K_{1,l_j}) \cap V(K_{1,l_{j'}}) = \emptyset$, for $j \neq j'$. 
Proof. The proof is a direct consequence of Proposition 2.2. □

A trivial upper bound on the injective edge chromatic number of a graph $G$ is its size, that is, $\chi'_i(G) \leq |E(G)|$. The Proposition 2.4 characterizes the graphs for which this upper bound is attained.

**Proposition 2.4.** Consider a graph $G$ of order $n$ and size $m$, with no isolated vertices. Then $\chi'_i(G) = m$ if and only if $G$ is complete.

Proof. Assume that $G$ is the complete graph $K_n$, and consider two arbitrary edges $e_i$ and $e_j$ of $K_n$. Then either $e_i$ is adjacent to $e_j$ and thus they are both included in a triangle or there exists an edge $e_k$ such that $e_i$, $e_j$ and $e_k$ are three consecutive edges. In any of these cases $e_i$ and $e_j$ must have different colors. Therefore, we have $\chi'_i(G) = n(n-1)/2 = m$.

Conversely, let us assume that $\chi'_i(G) = m$. Clearly $G$ has to be connected, since otherwise the same color could be used on edges from different components. If $G$ has size one then it is complete. Let us suppose that the size of $G$ is greater than one and $G$ is not complete. Since $G$ is connected, there are two adjacent edges in $G$ not lying in the same triangle. Coloring these two edges by the color $c_1$ and all the remaining edges differently, we produce an injective edge coloring with less than $m$ colors, which is a contradiction. Therefore $G$ is complete. □

3. $\omega'$ edge injective colorable graphs

The clique number of a graph $G$, denoted by $\omega(G)$, is the number of vertices in a maximum clique of $G$. Denoting the number of edges in a maximum clique of $G$ by $\omega'(G)$, it is immediate that $\omega'(G) = \omega(G)(\omega(G)-1)/2$.

**Proposition 3.1.** For any connected graph $G$ of order $n \geq 2$, $\chi'_i(G) \geq \omega'(G)$.

Proof. Let $K_r$ be a maximum clique in $G$. From Proposition 2.4, $\chi'_i(K_r) = r(r-1)/2 = \omega'(G)$. Therefore, we need at least $r(r-1)/2$ colors to color the edges of $G$, i.e., $\chi'_i(G) \geq r(r-1)/2 = \omega'(G)$.

Before to proceed let us recall the Turan’s theorem.

**Theorem 3.2 (Theorem of Turan [14]).** Let $G$ be a graph of order $n$ and size $m$, without a $q$-clique, with $q > 1$. Then,

$$m \leq \frac{(q-2)n^2}{2(q-1)}.$$  \hspace{1cm} (2)

As a consequence we have the following result.

**Corollary 3.3.** Let $G$ be a graph of order $n$ and size $m$, and consider a positive integer $q > 1$. Then

$$m > \frac{(q-2)n^2}{2(q-1)} \Rightarrow \chi'_i(G) \geq \frac{q(q-1)}{2}.$$  

Proof. From Theorem 3.2, $m > \frac{(q-2)n^2}{2(q-1)}$ implies that $G$ as a complete subgraph $K_q$, that is, $\omega(G) \geq q$. Therefore, $\omega'(G) \geq \frac{q(q-1)}{2}$ and from Proposition 3.1 we obtain $\chi'_i(G) \geq \frac{q(q-1)}{2}$. □

We say that $G$ is an $\omega'$ edge injective colorable ($\omega'$ EIC-)graph if $\chi'_i(G) = \omega'(G)$.

**Example 3.4.** The following graphs are examples of $\omega'$ EIC-graphs.

1. The complete graph, $K_n$.
2. The star, $K_{1,q}$.
If $G$ is a unicyclic graph with $K_3$, then $G$ is an $\omega'$ EIC-graph.

Proof. Let the vertices of the cycle $K_3$ be $v_1, v_2, v_3$, and the edges $e_1 = v_1v_2$, $e_2 = v_2v_3$, $e_3 = v_3v_1$. Color the edge $e_i$ with color $c_{i}$, for $i = 1, 2, 3$. Let $T_1$, $T_2$ and $T_3$ be the trees which are incident to $v_1$, $v_2$ and $v_3$, respectively, and color the edges of these trees as follows.

- Color the edges in $T_1$ which are adjacent to $c_1$, and call $C_1$ the set of these edges. Consider the edges in $T_1$ which are adjacent to $C_1$, and color all these edges with color $c_2$. Call $C_2$ the set of these edges. Now consider the edges in $T_1$ which are adjacent to edges of $C_2 \setminus C_1$, color these edges with color $c_3$, and call the set of these edges $C_3$. Again, consider the edges in $T_1$ which are adjacent to edges of $C_3 \setminus C_2$, color these edges with color $c_1$, and call the set of these edges $C_4$. Continue this procedure until all edges in $T_1$ have been colored.

- Color the edges in $T_2$ which are adjacent to $v_2$, and call the set of these edges $C_5$. Consider the edges in $T_2$ which are adjacent to $C_5$, color all these edges with color $c_3$, and call $C_6$ the set of these edges. Now consider the edges in $T_2$ which are adjacent to $C_6 \setminus C_5$, color these edges with color $c_1$, and call the set of these edges $C_7$. Again, consider the edges in $T_2$ which are adjacent to $C_7 \setminus C_6$, color these edges with color $c_2$, and call the set of these edges $C_8$. Continue this procedure until all edges in $T_2$ have been colored.

The result now follows from Proposition 3.1.
• Color the edges in \( T_3 \) which are incident to \( v_3 \) with color \( c_3 \) and call the set of these edges \( C_1^3 \). Consider the edges in \( T_3 \) which are adjacent to \( C_1^3 \) edges, color these edges with color \( c_1 \), and call the set of these edges \( C_1^1 \). Now consider the edges in \( T_3 \) which are adjacent to \( C_1^1 \) edges, color these edges with color \( c_2 \), and call \( C_1^2 \) the set of these edges. Again, consider the edges in \( T_3 \) which are adjacent to \( C_1^2 \setminus C_1^1 \) edges, color these edges with color \( c_3 \), and call the set of these edges \( C_1^2^3 \). Continue this procedure until all edges in \( T_3 \) have been colored.

This clearly produces a feasible 3 i-edge coloring of \( G \), and since 3 colors are needed for coloring the triangle \( K_3 \), we can conclude that \( \chi'_i(G) = 3 = \omega'(G) \), and the result follows.

4. Bounds on the injective chromatic index

Now we consider the injective edge coloring number of bipartite graphs.

**Proposition 4.1.** If \( G \) is a bipartite graph with bipartition \( V(G) = V_1 \cup V_2 \), and \( G \) has no isolated vertices, then \( \chi'_i(G) \leq \min\{|V_1|,|V_2|\} \).

**Proof.** The proof follows directly from Proposition 2.1 - item 3. \( \square \)

Note that the above bound is attained for every complete bipartite graph \( K_{p,q} \).

We now combine Proposition 4.1 with results from [3] on the 3-consecutive edge coloring of graphs to obtain bounds on the injective edge chromatic index for bipartite graphs.

Bujtás et. al [3] proved the following results.

**Proposition 4.2.** [3] If \( G \) is a bipartite graph with bipartition \( V(G) = V_1 \cup V_2 \), and \( G \) has no isolated vertices, then \( \max\{|V_1|,|V_2|\} \leq \psi'_3c(G) \leq \alpha(G) \), where \( \alpha(G) \) is the independence number of \( G \).

**Proposition 4.3.** [3] Let \( G \) be a graph of order \( n \).

- If \( G \) is connected, then \( \psi'_3c(G) \leq n - \frac{n-1}{\Delta(G)} \), where \( \Delta(G) \) denotes the maximum degree of \( G \);
- \( \psi'_3c(G) \leq n - i(G) \), where \( i(G) \) is the independence domination number of \( G \), i.e., the minimum cardinality among all maximal independent sets of \( G \).

From Propositions 4.1, 4.2 and 4.3 we can directly conclude the following.

**Corollary 4.4.** Let \( G \) be a connected bipartite graph of order \( n \geq 2 \). Then

\[
\begin{align*}
\chi'_i(G) & \leq n - \frac{n-1}{\Delta(G)}, \\
\chi'_i(G) & \leq n - i(G), \\
\chi'_i(G) & \leq \alpha(G).
\end{align*}
\]

Now we introduce an upper bound on the edge injective coloring number of a graph \( G \) in terms of its size and diameter, which we denote by \( \text{diam}(G) \).

**Proposition 4.5.** For any connected graph \( G \) of size \( m \geq 3 \), \( \chi'_i(G) \leq m - \text{diam}(G) + 2 \). This upper bound is attained if and only if \( G \) is \( P_{m+1} \).

**Proof.** Let \( P_d \) be a diametral path of \( G \). We can color the path \( P_d \) with 2 colors. Coloring all the other edges differently with \( m - \text{diam}(G) \) colors, we produce an injective edge coloring of \( G \), and then \( \chi'_i(G) \leq m - \text{diam}(G) + 2 \).

The proof of the last part of this proposition can be divided in two cases:
1. If \( G \) is a path, with \( n \geq 4 \), it follows from Proposition 2.1-item 1 that \( \chi'_i(P_n) = 2 \) and, since \( \text{diam}(G) = m \), the result holds.

2. Let us assume that \( G \) is not a path.

- If \( \text{diam}(G) \leq 2 \), Proposition 2.4 implies that
  \[ \chi'_i(G) < m - \text{diam}(G) + 2. \]
  In fact, if \( \text{diam}(G) = 1 \), then \( G \) is complete and thus \( m - \text{diam}(G) + 2 > m = \chi'_i(G) \). If \( \text{diam}(G) = 2 \), then \( G \) is not complete and thus \( m - \text{diam}(G) + 2 = m > \chi'_i(G) \).

- If \( \text{diam}(G) > 2 \), consider a diametral path \( P_d = x_1, \ldots, x_{d+1} \). Since \( G \) is connected and is not a path, then there exists a vertex \( u \notin V(P_d) \) which has (i) one, (ii) two or at most (iii) three neighbors in \( P_d \), otherwise \( P_d \) is not diametral.
  
  (i) Suppose \( u \) has a unique neighbor, say \( x_i \), in \( P_d \). As \( P_d \) is a diametral path, \( x_i \) has to be an interior vertex of \( P_d \), i.e., \( i \neq 1, d + 1 \), and the edges of \( P_d \) can be colored in a way such that \( x_{i-1}x_i \) and \( x_i x_{i+1} \) have the same color \( c \) and this color \( c \) can also be used for coloring the edge \( ux_i \). The remaining \( m - \text{diam}(G) - 1 \) edges can be colored with no more than \( m - \text{diam}(G) - 1 \) colors, and thus producing an \( i \)-edge coloring with at least \( 2 + 2 - \text{diam}(G) - 1 \) colors, and therefore \( \chi'_i(G) < m - \text{diam}(G) + 2 \).

  (ii) If \( u \) has two neighbors in \( P_d \), say \( x_i \) and \( x_j \), then they must have at most one vertex between them, i.e., \( j = i + 1 \) or \( j = i + 2 \). If \( j = i + 2 \), the two edges \( ux_i \) and \( ux_j \) can be colored with the same color, different from each of the two colors used for the edges of \( P_d \), and using a different color for each of the \( m - \text{diam}(G) - 2 \) other edges. Thus, \( \chi'_i(G) \leq 2 + 1 + m - \text{diam}(G) - 2 < m - \text{diam}(G) + 2 \). If \( j = i + 1 \), then use two colors to color the edges on path \( (P_d \setminus x_i x_j) \cup ux_i \cup ux_j \) a new color for edge \( x_i x_j \) and a different color for each of the remaining \( m - \text{diam}(G) - 2 \) edges. Again, \( \chi'_i(G) \leq 2 + 1 + m - \text{diam}(G) - 2 < m - \text{diam}(G) + 2 \).

  (iii) If \( u \) has three neighbors in \( P_d \), then they must be consecutive (otherwise \( P_d \) is not diametral), say \( x_i, x_{i+1}, x_{i+2} \). Coloring again the edges of \( P_d \) using two colors, say \( c_1 \) and \( c_2 \), edges \( ux_i \) and \( ux_{i+2} \) can be colored with an additional color \( c_3 \), and edge \( x_{i+1}u \) with a different color \( c_4 \). Using a different color for each of the \( m - \text{diam}(G) - 3 \), we can conclude that \( \chi'_i(G) \leq 2 + 1 + 1 + m - \text{diam}(G) - 3 < m - \text{diam}(G) + 2 \).

\[ \square \]

**Proposition 4.6.** For any tree \( T \) of order \( n \geq 2 \), \( 1 \leq \chi'_i(T) \leq 3 \).

**Proof.** If \( n = 2 \), \( \chi'_i(T) = 1 \). If \( n \geq 3 \), an edge can be added to \( T \) in such a way that the resulting graph \( H \) includes a triangle. We then have, \( \chi'_i(T) \leq \chi'_i(H) \), and using Proposition 3.6, \( \chi'_i(H) = 3 \). \[ \square \]

These lower and upper bounds are sharp. According to Proposition 2.3, the stars are the only connected graphs \( G \) such that \( \chi'_i(G) = 1 \). Regarding the upper bound, the tree \( T' \) of Figure 3 is a minimum size tree with \( \chi'_i(T') = 3 \).

![Figure 3: a minimum size tree T' with \( \chi'_i(T') = 3 \).](image)

Since for a subgraph \( H \) of a graph \( G \), any 3-consecutive edges of \( H \) are also 3-consecutive edges of \( G \), we have the following result.

**Proposition 4.7.** If \( H \) is a subgraph of a connected graph \( G \), then \( \chi'_i(H) \leq \chi'_i(G) \).

As an immediate consequence, we have the corollary below.
Corollary 4.8. Let $G$ be a connected graph of order $n$.

1. If $x$ is an edge of $G$, then $\chi'_i(G) \leq \chi'_i(G + x)$.
2. If $G$ includes a cycle $C_p$ and $4 \leq p \not\equiv 0 \pmod{4}$, then $\chi'_i(G) \geq 3$.
3. If $G$ includes a complete graph $K_p$, then $\chi'_i(G) \geq p(p - 1)/2$.
4. If $G$ includes the tree depicted in Figure 3, then $\chi'_i(G) \geq 3$.
5. If $G$ is a tree $T$, which includes the subtree $T'$ depicted in Figure 3, then $\chi'_i(T) = 3$.

In computer science a perfect binary tree is a tree data structure with exactly one vertex of degree two and where each of the other vertices has degree one or three. Now we have another corollary.

Corollary 4.9. Let $T$ be a perfect binary tree with $\text{diam}(T) \geq 7$. Then $\chi'_i(T) = 3$.

Proof. Note that every perfect binary tree $T$ with $\text{diam}(T) \geq 7$ has to include the tree depicted in Figure 3 as induced subgraph. Therefore, from Corollary 4.8 - item 5, the result follows. \qed

We proceed deriving a characterization of the injective edge chromatic index, which is checkable in polynomial time for trees.

Let $G$ be a graph of size $m \geq 1$, $\bar{G}$ the graph with $m$ vertices corresponding to the edges of $G$ and where, for every pair of vertices $x, y \in V(\bar{G})$, $xy \in E(\bar{G})$ if and only if there is an edge $e \in E(G)$ such that $x, e, y$ are consecutive edges of $G$. We obviously have the following.

Lemma 4.10. If $G$ is a graph of size $m \geq 1$, $\chi'_i(G) = \chi(G)$.

From Lemma 4.10 we can conclude the following.

Proposition 4.11. If $G$ is a graph of size $m \geq 1$, then $\chi'_i(G) \leq 2$ if and only if $\bar{G}$ is bipartite.

Proof. Note that the chromatic number of a graph with no edges is 1, and is equal to 2 if and only if it has at least one edge and is bipartite. Lemma 4.10 completes the proof. \qed

We therefore have the following characterization of graphs having injective edge chromatic index equal to 2.

Proposition 4.12. Let $G$ be a graph of size $m \geq 1$. Then, $\chi'_i(G) = 2$ if and only if $G$ is not a disjoint union of stars and $\bar{G}$ has no odd cycle.

Proof. Proposition 2.3 states that $\chi'_i(G) = 1$ if and only if $G$ is a disjoint union of stars. Proposition 4.11 states that if $\bar{G}$ is bipartite then $\chi'_i(G) \leq 2$. \qed

Taking into account Propositions 2.3 and 4.6, Proposition 4.12 reads for trees as follows.

Proposition 4.13. Let $T$ be a tree. Then, either

- $\chi'_i(T) = 1$ if $T$ is a star, or
- $\chi'_i(T) = 3$ if $T$ includes an odd cycle, or
- $\chi'_i(T) = 2$, in any other case.

For example, the graph $T'$, that is obtained from the tree $T'$ of Figure 3, which has $\chi'_i(T') = 3$, includes cycles $C_5$ and $C_7$.

Note that Proposition 4.13 gives a polynomial time algorithm to determine the injective edge chromatic index for trees.

The next result relates the injective edge chromatic index of a graph and of its square.

Let us denote the distance between the vertices $u$ and $v$ in $G$ by $d_G(u, v)$. The square of a simple graph $G$ is the simple graph $G^2$, where $e = uv$ is an edge in $G^2$ if and only if $d_G(u, v) \leq 2$. Using this concept and this notation we have the corollary.
Corollary 4.14. For any connected graph $G$, $\chi'_i(G) \leq \chi'_i(G^2)$.

Proof. Notice that $G$ is a subgraph of $G^2$. Therefore, applying Proposition 4.7, the result follows. \qed

Previously we have considered the unicyclic graphs which include a triangle and we proved that those are $\omega$ EIC-graphs. Now, the following proposition states a lower and upper bounds on the injective chromatic index of more general unicyclic graphs.

Proposition 4.15. Let $G$ be a unicyclic graph and $C_p$ the cycle in $G$. If $p \geq 4$, then $2 \leq \chi'_i(G) \leq 4$.

Proof. The left inequality follows directly from Proposition 2.1, item 2.

To prove that $\chi'_i(G) \leq 4$, let $v$ be an arbitrary vertex of the cycle $C_p$ and consider $G - v$ (the graph obtained from $G$ deleting $v$ and every edge of $G$ incident to $v$). As $G - v$ is a forest we can properly i-coloring its edges with three colors, say colors $c_1, c_2, c_3$. Now use a different color, say $c_4$, to color all edges of $G$ incident to vertex $v$. This is clearly a feasible i-edge coloring of $G$ using 4 color, showing that the result holds. \qed

Notice that the upper bound on the injective edge coloring number obtained in Proposition 4.15 is attained for the unicyclic graph $N$ depicted in Figure 5. Regarding the lower bound, it is attained for a graph $G$ if and only if $G$ is bipartite.

5. The injective chromatic index of some mesh graphs and cartesian products

Herein we call mesh graphs the graphs considered in [13]. Among these graphs we pay particular attention to the cartesian products $P_n \Box K_2$ and $P_r \Box P_s$ and also to the honeycomb graph. The Cartesian product $G \Box H$ of two graphs $G$ and $H$ is the graph with vertex set equal to the Cartesian product $V(G) \times V(H)$ and where two vertices $(g_1, h_1)$ and $(g_2, h_2)$ are adjacent in $G \Box H$ if and only if either $g_1 = g_2$ and $h_1$ is adjacent to $h_2$ or $h_1 = h_2$ and $g_1$ is adjacent to $g_2$.

Proposition 5.1. Let $P_n$ be a path of order $n \geq 3$. Then $\chi'_i(P_n \Box K_2) = 3$

Proof. Mark all the vertices in $P_n \Box K_2$ from the left to right as follows: mark the first upper vertex in the ladder by 1, the second lower vertex by 2, the third upper vertex by 3 and so on, as it is in Figure 4. Now color the edges with one end vertex labeled 1 by the color $c_1$, the edges with one end vertex labeled 2 by the color $c_2$, the edges with one end vertex labeled 3 by the color $c_3$ and so on. This coloring yields an injective edge coloring of $P_n \Box K_2$. Therefore, $\chi'_i(P_n \Box K_2) \leq 3$. On the other hand, it is easy to find $C_6$ as a subgraph of $P_n \Box K_2$ and, from Proposition 2.1-2, $\chi'_i(C_6) = 3$. Then, applying Proposition 4.7, it follows that $\chi'_i(P_n \Box K_2) \geq 3$. \qed

![Figure 4: The Cartesian product $P_n \Box K_2$ with $\chi'_i(G) = 3$.]

Before the next proposition it is worth to recall that a two dimensional grid graph is the graph obtained by the cartesian product $P_r \Box P_s$, where $r$ and $s$ are integers.

Proposition 5.2. If $r, s \geq 4$, then $\chi'_i(P_r \Box P_s) = 4$. 

Proof. Mark all the vertices in $P_r \Box P_s$ from the left to right as follows: mark the first upper vertex in the ladder by 1, the second lower vertex by 2, the third upper vertex by 3 and so on, as it is in Figure 4. Now color the edges with one end vertex labeled 1 by the color $c_1$, the edges with one end vertex labeled 2 by the color $c_2$, the edges with one end vertex labeled 3 by the color $c_3$ and so on. This coloring yields an injective edge coloring of $P_r \Box P_s$. Therefore, $\chi'_i(P_r \Box P_s) \leq 3$. On the other hand, it is easy to find $C_6$ as a subgraph of $P_r \Box P_s$ and, from Proposition 2.1-2, $\chi'_i(C_6) = 3$. Then, applying Proposition 4.7, it follows that $\chi'_i(P_r \Box P_s) \geq 3$.
Proof. We start to choose a color, say red, for the edges having the upper left corner vertex \( v \) of \( G = P_r \Box P_s \) as end vertex. Then, we color the edges having as end vertex the vertices which form a diagonal (starting at \( v \)) of the grid \( G \) alternating between red and another color, say green. The parallel diagonals are colored in the same way, using two different colors, say blue and yellow (see Figure 5). It is easy to check that this coloring produces an injective edge coloring of \( G \) and therefore, \( \chi'_i(G) \leq 4 \). Since the graph \( N \) depicted in Figure 5 is a subgraph of \( G \) such that \( \chi'_i(N) = 4 \), applying Proposition 4.7, it follows that \( 4 = \chi'_i(N) \leq \chi'_i(G) \leq 4 \).

![Figure 5: Injective edge coloring of \( G = P_r \Box P_s \) which has \( \chi'_i(G) = 4 \) and the unicyclic graph \( N \), where \( \chi'_i(N) = 4 \).](image)

Proposition 5.3. If \( G \) is a honeycomb graph, then \( \chi'_i(G) = 3 \).

Proof. Since the honeycomb graph \( G \) has a hexagonal tessellation, then \( C_6 \) is a subgraph \( G \) and, by Proposition 2.1-2, \( \chi'_i(C_6) = 3 \). Therefore, considering the coloring of the honeycomb graph \( G \) presented in Figure 6 which (as can be easily checked) is an injective edge coloring, it follows that \( 3 = \chi'_i(C_6) \leq \chi'_i(G) \leq 3 \).

![Figure 6: Injective edge coloring of a honey comb graph using three colors.](image)

Honeycomb graphs are hexagonal tessellations which appear in the literature as models of many applications. Among several examples presented in [13] we may emphasize the applications to cellular phone station placement, representation of benzenoid hydrocarbons, computer graphics and image processing, etc.

**Proposition 5.3.** If \( G \) is a honeycomb graph, then \( \chi'_i(G) = 3 \).

Proof. Since the honeycomb graph \( G \) has a hexagonal tessellation, then \( C_6 \) is a subgraph \( G \) and, by Proposition 2.1-2, \( \chi'_i(C_6) = 3 \). Therefore, considering the coloring of the honeycomb graph \( G \) presented in Figure 6 which (as can be easily checked) is an injective edge coloring, it follows that \( 3 = \chi'_i(C_6) \leq \chi'_i(G) \leq 3 \).

**Proposition 5.4.** For any connected graph \( G \) of order \( n \geq 2 \), \( \chi'_i(G \Box K_2) \leq n^2 - n \), and this bound is sharp. Furthermore, for any complete graph \( K_n \) with at \( n \geq 2 \), \( \chi'_i(K_n \Box K_2) = n^2 - n \).
Proof. Let $G'$ and $G''$ be the two copies of $G$ in $G \square K_2$. Give different colors to all edges in $G'$ and $G''$ say $1, 2, \ldots, m, m + 1, \ldots, 2m$, where $m \leq \frac{(n-1)}{2}$. Now consider the colorless edges in $G'$, all colorless edges of $G'$ have one end vertex in $G'$ and the other in $G''$. We can color these edges by the colors $1, 2, \ldots, m + 1$.

The $n$-cube $Q_n$ is defined repeatedly by $Q_1 = K_2$ and $Q_n = Q_{n-1} \square K_2$. Thus we have the following

**Corollary 5.5.** For the $n$-cube $Q_n$, $\chi'_i(Q_n) \leq 2^{(n-1)(n-1)}$.

### 6. Computational complexity of injective edge coloring

To establish the complexity of $i$-edge coloring we use a graph, denoted by $B_k$, which can properly be $i$-edge colored with $k$ colors. Graph $B_4$ is represented in Figure 7 from which it should be clear how to construct graph $B_k$, for arbitrary $k \geq 1$. Note that if we remove from $B_k$ all edges incident with $b_k$ and vertices $u_k, b_k, v_k$, we obtain $B_{k-1}$.

![Figure 7: Graph $B_4$](image)

As shown for $B_4$ in Figure 7, a feasible $k$ i-edge coloring of $B_k$ is obtained giving the same color to all the edges incident with each vertex $b_i$, and using different colors for edges incident with different $b_i$.

It can be easily verified that

**Lemma 6.1.** $\chi'_i(B_k) = k$. Moreover, in every feasible $k$ i-edge coloring of $B_k$ all edges incident with vertex $b_i$ receive the same color, $i = 1, \ldots, k$, and pairs of edges, one incident with $b_i$ and the other with $b_j$, $i \neq j = 1, \ldots, k$, receive different colors.

Proof. In any feasible i-edge coloring none of the colors of edges $u_k, b_k$ and $b_k, v_k$ can be used to color the edges incident with $b_i$ for $i = 1, \ldots, k - 1$. Taking into account that the edges of $B_{k-1}$ are the edges of $B_k$ not incident with $b_k$, this shows that $B_k$ cannot be properly i-edge colored with less than $k$ colors, thus implying $\chi'_i(B_k) = k$, and additionally that edges $u_i, b_i$ and $b_i, v_i$ must have the same color in any feasible i-edge coloring.

Since the color assigned to edge $u_i, b_i$ ($b_i, v_i$) cannot have the same color of edges $b_i, v_i$ ($u_i, b_i$), with $i = 1, \ldots, k - 1$, we can conclude that all edges incident with $b_k$ have the same color.

The remark above, noting that $B_{k-1}$ is obtained removing from $B_k$ all edges incident with $b_k$ and vertices $u_k, b_k, v_k$, completes the proof. $\square$
We now use Lemma 6.1 and the NP-completeness of deciding whether $\chi'(G) = k$, for $k \geq 3$ ([8, 10]), to establish the computational complexity of i-edge coloring.

**Theorem 6.2.** It is NP-complete to recognize graphs having edge injective chromatic number equal to positive integer $k \geq 3$.

Proof. Given an arbitrary graph $G$ with maximum degree $\Delta(G) = k$, we construct graph $G(B_k)$ replacing every edge $uv$ of $G$ by graph $B_k$, such that each edge $uv$ of $G$ is now the edges $u_b v_b$ and $b_b v_b$ of $B_k$. Therefore, in the modified graph $G(B_k)$ we have a graph $B_k$ for each edge of $G$. Given a $k \geq 3$ edge coloring of $G$ we obtain a $k$ i-edge coloring of $G(B_k)$ by (i) assigning the color used on each edge $uv$ of $G$ to every edge incident with vertex $b_b$ of subgraph $B_k$ of $G(B_k)$ corresponding to edge $uv$; and (ii) using the remaining $k - 1$ colors to feasibly i-edge color the other edges of $G(B_k)$. Clearly, the resulting $k$ i-edge coloring of $G(B_k)$ is feasible if and only if the $k$ edge coloring of $G$ is feasible.

Conversely, given a feasible $k \geq 3$ i-edge coloring of $G(B_k)$, where each subgraph $B_k$ corresponding to each edge of $G$ has exactly $k$ colors, we obtain a feasible $k$ edge coloring of $G$ assigning to every edge $uv$ of $G$ the color used on the edges incident with $b_b$ of the subgraph $B_k$ of $G(B_k)$ corresponding to $uv$.

We thus have $\chi'(G) = \chi'_3(G(B))$. Finally, since recognizing graphs $G$ with edge injective chromatic number, $\chi'_3(G)$, equal $k$ is obviously in NP, the result follows. □

7. Conclusions and open problems

In this paper we have characterized graphs having injective chromatic index equal to one (Proposition 2.3) and two (Proposition 4.12), and graphs with injective chromatic index equal to their sizes (Proposition 2.4). These graphs are recognized in polynomial time. We showed that trees have injective chromatic index equal to 1, 2 or 3 (Proposition 4.13), and identified the trees $T$ with $\chi'_i(T) = i$, for $i = 1, 2, 3$ (Proposition 4.13).

In Section 3, we have introduced the notion of $\omega'$ EIC-graphs (for which $\chi'_3(G) = \omega'(G)$) and presented a few examples of these graphs. Following the results published in [4], a few additional families of these type of graphs (therein called perfect $\omega'$ EIC-graphs) were constructed in [15]. However, the characterizations of $\omega'$ EIC-graphs remains open.

Some lower and upper bounds on the injective chromatic index of a graph were obtained in Section 4.

Regarding mesh graphs, in Section 5, the injective chromatic index of the cartesian products $P_n \sqcap K_2$ and $P_1 \sqcap P_4$ as well as the honey comb graphs were determined. However, it is not known the injective chromatic index of several other mesh graphs as it is the case of hexagonal mesh graphs (see [13, Fig. 2]). It is also open to compute the injective chromatic index for planar graphs.

Finally, in Section 6, we have proved that determining the injective chromatic index of graphs is NP-hard.
